Abstract

Implant treatment is regarded as a safe technique with high rates of success. Nevertheless, it has, as every surgical procedure, several complications that can occur and that must be known in order to prevent or solve them. Implant surgery complications are frequent occurrences in dental practice and knowledge in the management of these cases is essential. While dental implants are increasingly becoming the choice of replacement for missing teeth, the impediments associated with them are progressively emerging too. The aim of this review was to highlight the challenges of treatment plan-related, anatomy related and procedure-related surgical complications as well as to discuss the etiology, management and treatment options to achieve a satisfactory treatment outcome.

INTRODUCTION

Dental implant therapy is a well-established dental treatment modality that provides benefits for edentulous and partially edentulous patients. Edentulism is a toothless condition that affects well-being and life quality. Although the prevalence of complete tooth loss has declined since 2002, edentulism remains a major disease worldwide, especially among older adults.1 Studies have demonstrated that dental caries and periodontal diseases are frequent reasons for tooth extraction 2–5. Survival rates of dental implants are reported to be very high in the recent literature [6-9]. These rates seem to indicate minimal complications with dental implants, however, careful consideration should be taken prior to implant placement as peri-implantitis and other problems can be encountered [10,11]. It is important to note the difference between implant survivals and implant success. Implant survival describes an implant that an implant that is still in place. It does not consider factors such as mobility, bone loss, peri-implant disease, and so on. Alternatively, implant success defines an implant that is healthy and fully functional within the oral cavity [12]. When other factors such as bone loss are considered, long term follow up of dental implants may reveal success rates lower than the reported survival. Smoking, male gender, edentulism, implant diameter, and bone augmentations are previously identified risk factors for early implant failure [13]. The aim of the current review is to discuss specific complications associated with dental implants.
Complications Associated With Dental Implants

The majority of problems that can arise in an implantology treatment are accidents, complications or iatrogenic errors, and are a consequence of an inadequate indication, poor quality or quantity of bone, an erroneous surgical technique, infections, lack of oral hygiene, smoking habit, systemic diseases that were poorly controlled. Poor patient selection is one of the important factors that adversely contribute toward failures in implant dentistry [14].

Screw loosening

Goodacre et al. [15] stated that screw loosening or fracture prevailed more with the prosthetic screws as opposed to the abutment screws. Implants restored with single crowns have shown more screw loosening as compared to multiple implants with multiple restored units, and mandibular molar implant restorations are more affected by screw loosening as compared to the maxillary ones. Over the course of years, many manufacturers have revised the conventional implant components to reduce the incidents of screw loosening [16].

Implant displacement

The invasion of the maxillary sinus by an implant can occur during or after the surgery as a result of an insufficient primary stability. It has been reported a case of an implant which had been implanted 9 months earlier during a maxillary sinus lift surgery, and which was found inside the sinus only a few days after having placed the fixture.

Mandibular fracture

Mandibular fracture, during implant placement, is associated with atrophic mandibles. The central area of the mandible has a greater risk for this complication because it has a poor vascular irrigation, which sometimes makes very difficult for the bone and peristemeum to provide enough blood for the healing process derived from an implant placement.

Screw/implant fracture

There are two major causes of implant fracture: biomechanical overloading and peri-implant vertical bone loss [17]. The risk of implant fracture increases multifold when the vertical bone loss is severe enough to concur with the apical limit of the screw [19, 20].

Implant fractures are also attributable to flaws in the designs and manufacturing of implant itself [21]. Unnoticed and recurrent screw loosening is a risk factor for dental implant fracture, which indicates change in the prosthesis design [22].

Cement failure

Cement failure is another consequence of biomechanical overload, typically affects the prosthesis attachment and may be treated by recementation procedure [21].

Nerve Injury

When placing implants in the mandible, proper radiographs and pretreatment planning must be done to ensure complete aversion of the inferior alveolar, mental, incisive or lingual nerves. If the mandibular canal cannot be seen on a panoramic radiograph, a computer tomography (CT) scan should be taken to verify the location. The potential risks and complications of injury or damage to these vital structures should be included on the informed consent to avoid liability in cases of lawsuits.

Bartling et al. [24] observed 405 mandibular endosseous implants placed in 94 patients to determine the incidence of altered sensation using standard neurologic tests over a 6-month period. An incidence of 8.5% was found at the first postoperative appointment.
Only 1 patient experienced complete anesthesia for 2 months. This was later resolved by 4 months.

**Cortical Plate Perforation**

The buccal cortical plate varies in thickness throughout the mouth and traumatic dental extractions can cause markedly thin plates or concavities, as well as overall ridge width deficiency [25].

**Sinus Membrane Complications**

In the maxillary posterior, the proximity of the sinuses 26 27 can create a problem for dental implants if there is minimal residual crestal bone (5 mm) for stability. The maxillary sinus lift technique is an accepted procedure, demonstrated by Tatum, 28 to augment vertical height in the severely resorbed posterior maxilla area to facilitate proper implant placement. Sinus complications often occurred when the membrane is perforated at time of surgery.

**Peri-implantitis**

Biological failures include bacterial infections, microbial plaque buildup, progressive bone loss, and sensory disruptions [29, 31]. Biological complications are subcategorized into early biological failures and late implant failures, where the early failures are attributed to the failure of placing the surgical implant under proper aseptic measures [31, 34] and the late complications are typically peri-implantitis and infections bred by bacterial plaque [35,36]. The peri-implant disease is also related to unequal occlusal load distribution, which may lead to loosening of the superstructure, infection of the surrounding area, eventually culminating into the inflammatory process [36]. Predisposing systemic conditions include uncontrolled diabetes mellitus, osteoporosis, smoking, long-standing treatment with steroids, uncontrolled periodontitis, radiation therapy, and chemotherapeutics [37, 38].

Clinical and radiographic symptoms of peri-implantitis [38]

- Probing depth <6 mm
- Bleeding on probing/suppuration
- Attachment loss/bone loss of 2.5 mm
- Vertical destruction of crestal bone on radiographs
- Possible swelling and hyperplasia of the peri-implant tissues
- Pain (unusual) if present, depicts acute infection

**Esthetic Complications**

Esthetic complications are common in implant therapy. These complications can include shade and contour issues and problems with recession, abutment margin placement, and implant positioning in the occlusogingival or mesiodistal dimensions [39].

**Conflicts of interest**

There are no conflicts of interest.

**CONCLUSION**

Despite the popularity of dental implants, the surgical placement of these implants is not a riskless procedure. Complications of dental implants are not obsolete and dental implant associated problems may not be apparent immediately. Proper training and planning are necessary in order to avoid complications. In the event that complications do arise, the surgeon should be equipped and knowledgeable to handle the emergency. To conclude, clinicians should develop new concepts in implant therapy considering all biologic and biomechanical factors, in conjunction with continuous training and improvement of their surgical skills to control and prevent implant complications. It is strongly recommended to avoid use of the many different implant systems without in-depth knowledge of the surgical and prosthetic armamentarium or thoughtful evaluation of each individual system.
